I see. I will try and sort it out.

But I am also facing another problem with my analysis.

I have my dependent variable defined as the number of infant deaths occurring to women who ever had any births. It is a women level data (IR) file and I am intending to check determinants of these deaths.

I have very correctly made my dependent variable, but have a problem in defining independent variables. For example, my independent variable is preceding birth interval, or immunization status, or anything related to children has distinct entries for every kid. I am not sure how to use a separate variable for each kid, even averages don't seem to be a reliable option.

Can you help me in telling what should I do about it? Is merging a way out, or taking averages, or something else?
